Abstract

Pseudo-code for the simplex projection algorithm [1] and the S-map algorithm [2]. Algorithms are presented for the simple case of predicting one variable using its own time series.

1 Notation

- E denotes the embedding dimension.

- k denotes the number of nearest neighbors we use. For the simplex method, the default is $k = E + 1$ but for the S-map method it can be much larger.

- T_p denotes how many time-steps into the future we are trying to predict.

- $X \in \mathbb{R}$ denotes a (potentially long) time series.

- $y \in \mathbb{R}^E$ is a vector of lagged observations for which we want to make a prediction — in the simplest case where all components of the vector are single time step lags, y_1 represents the current value, y_2 is the value one time step prior and y_E is the value $E - 1$ time steps prior.

- $\theta \geq 0$ is the tuning parameter in the S-map method.

- $X_t^E = (X_t, X_{t-1}, \ldots, X_{t-E+1})' \in \mathbb{R}^E$ denotes the lagged embedding vectors.

- $\|v\|$ is an unspecified norm of v. We do not specify which norm to use and that choice is left to the user / reader.

- $\|v\|_2^2 = \sum_i v_i^2$ is the squared L2-norm (squared Euclidean distances).

- Entries of matrices and vectors are indexed in the standard linear algebraic fashion, starting at 1 (like the R standard) and not at 0 (like the C/C++ and python standard).

2 Helper Methods

2.1 Nearest neighbors

I will not write implementation of the nearst neighbors method, just present its description. The method will be used with the signature presented in algorithm 1.

The input variables X, y and k are defined in section 1. The method returns a list of indices $N = \{N_1, \ldots, N_k\}$ such that

$$\|X_{N_i}^E - y\| \leq \|X_{N_j}^E - y\| \text{ if } 1 \leq i \leq j \leq k,$$

Algorithm 1 Find Nearest neighbors

1: **procedure** NEARNEIGHBOR(y, X, k)

2.2 Least Squares

A least squares method finds x that minimizes the error in the solution of an over-determined linear system (more equations than variables). Below, $A \in \mathbb{R}^{p \times q}, p > q$ and $b \in \mathbb{R}^p$ and the least squares problem is to find

$$\hat{x} := \operatorname*{arg\,min}_{x \in \mathbb{R}^q} \|Ax - b\|_2^2.$$

This problem can be solved using a Singular Value Decompostion (SVD), as outlined in algorithm 2.

Algorithm 2 Least Squares via SVD

1: **procedure** LEASTSQUARES(A, b) $\triangleright$ Assume $A \in \mathbb{R}^{p \times q}, p > q$.
2:      $U, S, V \leftarrow \text{SVD}(A)$ $\triangleright$ Thus, $A = USV'$
3:      $S^{inv} \leftarrow \text{ZEROS}(q, p)$ $\triangleright$ The zero matrix in $\mathbb{R}^{q \times p}$
4:      **for** $i = 1, \ldots, q$ **do**
5:          **if** $S_{ii} > 10^{-5} S_{11}$ **then** $\triangleright$ Note that 10^{-5} is arbitrary
6:             $S_{ii}^{inv} \leftarrow \frac{1}{S_{ii}}$
7:      $x \leftarrow VS^{inv}U'b$
8:      **return** x
---

3 Simplex Projection

Ignoring ties in distances, minimal distances, minimal weights and other potential hazards, the following algorithm performs Simplex projection to predict T_p time-steps ahead.

Algorithm 3 Simplex Projection [1]

1: **procedure** $\textsc{SimplexPrediction}(y, X, E, k, T_p)$
2: $\quad N \leftarrow \textsc{NearNeighbor}(y, X, k)$ $\qquad\qquad\quad$ ▷ Find k nearest neighbors.
3: $\quad d \leftarrow \|X_{N_1}^E - y\|$ $\qquad\qquad\qquad\qquad$ ▷ Define the distance scale.
4: $\quad$ **for** $i = 1, \ldots, k$ **do**
5: $\qquad w_i \leftarrow \exp(-\|X_{N_i}^E - y\|/d)$ $\qquad\qquad$ ▷ Compute weights.
6: $\quad \hat{y} \leftarrow \sum_{i=1}^k \left(w_i X_{N_i + T_p} \right) / \sum_{i=1}^k w_i$ ▷ prediction = average of predicitions.
7: $\quad$ **return** $\hat{y}$

---

4 S-map

Ignoring ties in distances, minimal distances, minimal weights and other potential hazards, the following algorithm uses the S-map method to predict T_p time-steps ahead.

Algorithm 4 S-map [2]

1: **procedure** $\textsc{SmapPrediction}(y, X, E, k, T_p, \theta)$
2: $\quad N \leftarrow \textsc{NearNeighbor}(y, X, k)$ $\qquad\qquad$ ▷ Find NN to use for prediciton.
3: $\quad d \leftarrow \frac{1}{k} \sum_{i=1}^k \|X_{N_i}^E - y\|$ $\qquad\qquad\qquad$ ▷ Sum of distances.
4: $\quad$ **for** $i = 1, \ldots, k$ **do**
5: $\qquad w_i \leftarrow \exp(-\theta\|X_{N_i}^E - y\|/d)$ $\qquad\qquad$ ▷ Compute weights.
6: $\quad W \leftarrow \operatorname{diag}(w_i)$ $\qquad\qquad\qquad\qquad\quad$ ▷ Reweighting matrix.
7: $\quad A \leftarrow \begin{bmatrix} 1 & X_{N_1} & X_{N_1-1} & \ldots & X_{N_1-E+1} \\ 1 & X_{N_2} & X_{N_2-1} & \ldots & X_{N_2-E+1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & X_{N_k} & X_{N_k-1} & \ldots & X_{N_k-E+1} \end{bmatrix}$ $\qquad$ ▷ Design matrix.
8: $\quad A \leftarrow WA$ $\qquad\qquad\qquad\qquad\qquad$ ▷ Weighted design matrix.
9: $\quad b \leftarrow \begin{bmatrix} X_{N_1+T_p} \\ X_{N_2+T_p} \\ \vdots \\ X_{N_k+T_p} \end{bmatrix}$ $\qquad\qquad\qquad\qquad$ ▷ Response vector.
10: $\quad b \leftarrow Wb$ $\qquad\qquad\qquad\qquad\qquad$ ▷ Weighted response vector.
11: $\quad \hat{c} \leftarrow \arg\min_c \|Ac - b\|_2^2$ $\quad$ ▷ Least squares, can be solved via algorithm 2.
12: $\quad \hat{y} \leftarrow \hat{c}_0 + \sum_{i=1}^E \hat{c}_i y_i$ $\qquad$ ▷ Using the local linear model $\hat{c}$ for prediction.
13: $\quad$ **return** $\hat{y}$

Note that k, the number of nearest neighbors used for prediciton, can be very large compared to the embedding dimension E. Since $A \in \mathbb{R}^{k \times (1+E)}$, this means that A is "tall and skinny" and the system $Ac = b$ is *over-determined* (it has more equations than variables). This means (typically) that there does not exist any unique c that solves said system. This is why we seek a least-squares solution instead.
